

While the provided sources do not include raw MQL5 code, they detail the exact algorithmic logic required to calculate the Point of Control (POC) strictly on the back end.

To implement the POC calculation natively in MQL5, you must program your Expert Advisor to execute the following mathematical steps:

1. **Define the Lookback Range:** Specify the exact number of recent historical bars or the time period your EA will analyze 1, 2.
2. **Determine the Price Boundaries:** Scan the chosen period to extract the absolute minimum and maximum prices 3.
3. **Generate Price Bins (Arrays):** Divide this high-to-low price range into a specific number of discrete mathematical "bins" or rows (such as the 400 rows you previously specified) to define the granularity of the profile 1, 3.
4. **Pull the Volume Data:** Configure your EA to pull either actual Real Volume (for exchange-traded instruments) or Tick Volume (used as a highly accurate proxy in Forex) 1, 4.
5. **Prorate and Distribute Volume:** Loop through every candlestick in the defined range and apportion its volume across the corresponding price bins 3. Your algorithm must **prorate the volume proportionally** if a candle spans multiple levels, calculating the distinct contributions from the candle's body, upper wick, and lower wick 1, 3.
6. **Identify the POC:** Once all volume is distributed into the arrays, mathematically scan the bins to find the single price level that contains the **highest accumulated volume** 4, 5. This bin is your Point of Control 1.

**The iCustom() Alternative** If you want to save processing resources and avoid coding the complex array-sorting logic from scratch, you can use the MQL5 iCustom() function to call an existing indicator in the background. For example, the *Volume Profile Indicator by EarnForex* is specifically coded with an **output buffer for the Point of Control (POC)** 6. This allows your EA to silently read the live POC value as a data feed without rendering any visual charts 6.
